Imaging of varicoceles

BY JANE BELFIELD

A varicocele is a collection of dilated, tortuous spermatic veins of the pampiniform venous plexus. It is seen in 10-15% of the general population and is associated with both primary and secondary infertility. A varicocele is the most common cause of correctable male infertility. Patients are usually asymptomatic but may present with a painless scrotal swelling, scrotal pain or describe a ‘heavy sensation’, but a clinically asymptomatic varicocele may also be diagnosed during infertility investigations.

Due to the angle at which the left testicular vein enters the left renal vein, most varicoceles are left-sided. Varioceles are left-sided in 78%, right-sided in 6% and bilateral in 15%. A varicocele may be primary, which are usually idiopathic, or secondary, usually due to incompetent or congenitally absent valves in the testicular vein. Secondary varicoceles due to occlusion of the left spermatic vein are less common and are due to increased pressure from compression of the testicular vein, obstruction of the vein or splenorenal shunting.

This article aims to outline imaging findings and briefly describe embolisation of varicoceles.

Physical examination

Varicoceles are graded according to physical examination, which is usually performed with the patient both in the supine and the erect position. Examination should be undertaken both at rest and during the Valsalva manoeuvre [1].

The grading system used by Dubin and Amelar is based on the clinical features during the examination [2]:

- Grade 0 – moderate, transient venous reflux that ends before Valsalva manoeuvre.
- Grade 1 – persistent venous reflux during Valsalva manoeuvre but not otherwise.
- Grade 2 – palpable at rest, but not visible.
- Grade 3 – visible and palpable at rest.

Ultrasound

Ultrasound is the recommended first-line investigation as it is relatively quick, cheap and non-invasive [3]. Doppler ultrasound, used to assess flow, has a reported sensitivity of 97% and specificity of 94% for varicoceles [4]. However, a subclinical varicocele that is diagnosed by ultrasound is not sufficient evidence for treatment.

Unlike the physical examination most ultrasounds are performed with the patient in the supine position. However, some authors advise that they should also be assessed whilst the patient is in the standing position [5].

Other imaging modalities include venography, radionuclide tests and MRI, but these are not recommended in routine practice.

Blood vessels in the pampiniform plexus are usually no more than 1.5mm in diameter. Ultrasound of a varicocele will show dilated, tortuous tubular structures in the paratesticular region. They may be anechoic or contain echogenic material, depending on the speed of flow within the varicocele (Figure 1). The calibre of the vessels used to define a varicocele varies in the literature from 2mm to 3mm [6].

When the patient is at rest, the flow within the vessels may be too slow to detect on colour Doppler ultrasound, and the Valsalva manoeuvre is used. Patients are asked to ‘bear down’ during the ultrasound examination and then relax, and images are taken both with the patient at rest and during the Valsalva manoeuvre. If a varicocele is present, the vessels will enlarge and should demonstrate reversal of flow (Figure 2).

There are several systems for classification of varicoceles on ultrasound and many centres use the Dubin classification, which is based on findings with the patient scanned in the supine position:

- Grade 0 – moderate, transient venous reflux during Valsalva manoeuvre.
- Grade 1 – persistent venous reflux throughout the entire Valsalva manoeuvre.
- Grade 2 – persistent venous reflux that is present under resting conditions and does not change during Valsalva manoeuvre.

When assessing for a varicocele on ultrasound, the main features to look for are:

- Dilatation of the pampiniform plexus veins >2-3mm in diameter.
- Serpiginous appearance.
- Reversal of flow with Valsalva manoeuvre.

Intratesticular varicocele

Intratesticular varicoceles are rare, occurring in approximately 2% of symptomatic patients. Most intratesticular varicoceles occur on the left, and are usually associated with an ipsilateral
extratesticular varicocele. Patients may present with pain due to stretching of the tunica albuginea due to congestion of the intratesticular veins. There is an increased incidence in men who have undergone orchidopexy for undescended testis [7].

Dilated intratesticular veins are seen, which are usually adjacent to the mediastinum testis. On grey-scale ultrasound, this will appear as an anechoic tubular structure, which may have a similar appearance to an intratesticular cyst or tubular ectasia (Figure 3) and it is imperative to apply Doppler ultrasound in order to assess for vascularity (Figure 4). The flow within the varicocele will again be shown to increase and demonstrate reversal of flow when Valsalva manoeuvre is applied (Figure 5).

**Left renal tumours**

Due to the insertion of the left testicular vein into the left renal vein, previously if a left-sided varicocele was diagnosed on ultrasound, many operators evaluated the left kidney at the same time to exclude a renal tumour. There is poor evidence to support the routine scanning of the left kidney in all patients with a varicocele. Recent review of the evidence suggests that if a patient has a retroperitoneal tumour, it will present in other ways before a varicocele develops, and young patients with a varicocele will only very rarely have a retroperitoneal tumour. Therefore although a renal tumour can cause a left-sided varicocele, scanning the left kidney is only indicated in patients over the age of 40 years with an acute presentation of a varicocele [8].

**Embolisation of varicoceles**

Spermatic venography is usually reserved for patients who require surgical or radiological intervention and many varicoceles are now treated radiologically with occlusion of the internal spermatic vein. Treatment is usually only performed in patients who are symptomatic or who have been undergoing infertility investigations. There are no set radiological criteria for referral for treatment such as the calibre of vessels, and referrals are made on clinical grounds. Evidence shows that although markers of semen quality, such as sperm count, improve following treatment, the overall fertility rates do not improve.

Possible methods of treatment include sclerosing agents, metallic coils and detachable balloons. This is minimally invasive and has a faster recovery time compared with surgical repair and can be performed under local anaesthetic. The left spermatic vein is cannulated (Figure 6) and coils, or other material to be used, inserted and then the vein is reassessed to ensure the varicocele has been treated (Figure 7). Five to ten percent of varicoceles recur after embolisation and therefore it is recommended that patients undergo a routine ultrasound in approximately four weeks to ensure the varicocele has not returned.

**Conclusion**

Ultrasound is the imaging investigation of choice for assessment of varicoceles. It should be remembered that a lot of operators do not assess the patient in the standing position, but instead use the Valsalva manoeuvre to assess for enlargement of the vessels and reversal of flow.
